Cognitive

ABSTRACT

There is convergent evidence that natural environments allow restoration from stress. This randomised, cross-over, field-based trial compared psychological and physiological responses of unstressed individuals to self-paced 30-min walks in three pleasant environments: residential (urban), natural (green), and natural with water (blue). Changes from baseline (T1) to T2 (end of 30-min walk), and T3 (30 min after leaving environment) were measured in terms of mood, cognitive function, restoration experiences, salivary cortisol, and heart rate variability (HRV). In the final sample ($n = 38$; 65% male; mean age 40.9 ± 17.6 years), mood and cortisol improved at T2 and T3 in all environments. Green and blue environments were associated with greater restoration experiences, and cognitive function improvements that persisted at T3. Stress reduction (mood and cortisol changes) in all environments points to the salutogenic effect of walking, but natural environments conferred additional cognitive benefits lasting at least 30 min after leaving the environment.

1. Introduction

There is a convergent evidence for a positive relationship between natural environment exposure and health (Hartig, Mitchell, de Vries, & Frumkin, 2014). Commonly posited explanatory mechanisms include increased opportunities for physical activity and social interaction from active use of natural environments, stress reduction and cognitive restoration of passive or active use, and mitigation of environmental pollutants, such as noise and air pollution (Bowler, Buyung-Ali, Knight, & Pullin, 2010; Hartig et al., 2014; Nieuwenhuijsen et al., 2014).

Experimental studies to characterise the benefits of engaging with natural environments have typically departed from one of two theoretical standpoints: attention restoration theory (ART), which proposes that nature allows restoration from directed attention fatigue and enables more effective cognitive performance (Kaplan, 1995); stress reduction theory (SRT), where natural environments are thought to influence affective states by promoting recovery

from stress, and diminishing arousal and negative thoughts through psycho-physiological pathways (Ulrich, 1983; Ulrich et al., 1991).

ART is well supported by data from laboratory-based image viewing studies (Berto, 2005; Staats, Kieviet, & Hartig, 2003; van den Berg, Koole, & van der Wulp, 2003) and some field studies (Berman, Jonides, & Kaplan, 2008; Hartig, Evans, Jammner, Davis, & Gärling, 2003; Sonntag-Öström et al., 2014; Tennessen & Cimprich, 1995) showing that attention, measured as performance at cognitive tasks, is better when individuals are exposed to natural rather than urban environments. For SRT, evidence to date suggests that viewing or visiting natural environments can result in better affective outcomes measured through self-reported mood scales (Bowler et al., 2010; Lee et al., 2011; Tsunetsugu et al., 2013; Tyrväinen et al., 2014), perhaps more so when the natural environment contains water, such as a river, lake or coast (Barton & Pretty, 2010).

There is growing interest in measuring corresponding physiological responses to natural environments, particularly in field (rather than laboratory) studies, where the experiences of participants in the environments can be more ecologically valid and typically involve walking (sometimes in addition to sitting) in

urban and natural environments. To date, the evidence remains less conclusive (Bowler et al., 2010). Physiological measures in field experiments have been used to characterise cardiovascular (e.g., heart rate, blood pressure, heart rate variability) and neuroendocrinal (e.g., cortisol, salivary amylase) responses, and more recently, brain activity (Aspinall, Mavros, Coyne, & Roe, 2015). There is evidence that walking in natural environments can lower blood pressure (Hartig et al., 2003), but evidence for stress lowering effects of walking in natural environments measured through reduced cortisol concentrations, is inconsistent (Beil & Hanes, 2013; Bowler et al., 2010; Lee et al., 2011; Park, Tsunetsugu, Kasetani, Kagawa, & Miyazaki, 2010). Similarly, despite support from laboratory studies involving walking in simulated environments (Annerstedt et al., 2013) and from seated image viewing studies (Brown, Barton, & Gladwell, 2013; Gladwell et al., 2012), there is not strong support for beneficial heart rate variability (HRV) responses to natural versus urban environments from field experiments (Bowler et al., 2010). Overall, our understanding of the cardiovascular and neuroendocrinal responses to natural environments in field studies remains limited.

We present data from a field-based, randomised, cross-over experiment that addresses the call for robust experimental examination of psycho-physiological responses to natural environments (Bowler et al., 2010) and contributes to the emerging literature in a number of ways. First, it is not uncommon for field studies in this area to use comparator urban environments that are inherently *stressful*. We avoided using busy commercial areas and main roads with high traffic volumes for our urban comparator, to reduce the risk of detecting negative responses to the urban condition, rather than positive responses to natural environments (Hartig et al., 2003; Lee et al., 2011; Park et al., 2010; Tsunetsugu et al., 2013; Tyrväinen et al., 2014). Second, we explored *instorative* effects of natural environments, which have been described as the benefits that 'do not necessarily follow a reduction in adaptive capacities nor involve restoring diminished capacities' (Hartig, 2007, p.2). Rather than focussing on restoration from a *stressed* or *depleted* baseline state, our interest is the potential for natural environments to promote psycho-physiological improvements in a non-stressed, healthy adult sample, as engagement with natural environments may have wider public health benefits than facilitating recovery from stress or directed attention fatigue. Third, we controlled for potential confounding effects of social interaction and physical activity. Finally, our experimental design enabled enquiry beyond the immediate exposure effects to understand whether any immediate benefits were sustained once people left the environment.

The overarching study aims were to: (i) to compare psycho-physiological responses to natural environments with and without water, and a pleasant urban environment; (ii) explore the immediate and sustained *instorative* potential of natural environments. In the context of existing research, it was hypothesised that natural environments would confer more favourable responses than urban, with strongest effects in natural environments with water present. However, given our focus on healthy, unstressed individuals, and a pleasant urban comparator environment, it was hypothesised that such effects might be less pronounced than reported elsewhere.

2. Method

2.1. Participants

Participants were adults who lived, worked or studied in a medium size conurbation in the West Midlands region of the UK. Inclusion criteria were: aged ≥ 18 years; non-smokers; not pregnant; no chronic medical conditions; not taking medication that

will influence cortisol or heart rate variability (Granger, Hibel, Fortunato, & Kapelewski, 2009); 'healthy' based on self-report (SF12v2) (Quality Metric, 2006); and able to walk for 30 min.

2.2. Design and procedure

Data were collected between June and October 2013. We used a randomised, cross-over, within-subjects design, whereby all participants walked for 30 min in each of three environments (Fig. 1) at the same time on three days. Data were always collected on weekdays (Mon–Fri) and, where possible, all three days completed within two weeks (depending on participant availability). The order of environmental exposures was individually randomised by ascribing a number of 1–6 to represent each possible environment combination, which was then assigned to the participant using a random number generator (MS Excel). Although participants were not given prior warning of the order in which environments would be visited, *blinding* of allocation was not relevant given the nature of the trial (i.e., exposures involved visiting an environment; all participants visited all environments). Environment visits were only conducted in temperate conditions and were re-arranged in the event of rain/inclement weather conditions. Two researchers (GH, DM) controlled these procedures, with the same researcher being assigned to participants for all of their environmental visits.

Participants were recruited through local media, advertising in and around the University campus, and a mail shot to households within 1 km of the campus, with eligibility screening via an online survey. This approach was intended to improve generalisability, rather than delimiting to a student sample. Eligible participants were invited to attend the University at either 12:00 or 14:00 on each day, and to refrain from consuming caffeine or food for at least 60 min prior to arrival. Fig. 2 illustrates the procedures on each of the three days of data collection. Briefly, following baseline measures (T1), participants were transported to the environment to walk along a pre-designated route, at a self-directed pace. Self-pacing was used to optimise participant experience and ecological validity, and walking helped to ensure that exercise intensity was of mostly light intensity (approaching moderate intensity for some). A researcher (GH or DM) accompanied the participant on the walk, remaining half a stride behind to allow the participant to determine the pace. Participants were asked for their Rate of Perceived Exertion (RPE) at 5-min intervals, with no other social interaction. After 30 min, follow-up measures were taken (T2), and repeated a further 30 min later after returning to the University (T3). Participants were offered a £40 retail voucher in appreciation of their time. All study procedures were approved by the University Ethics Committee.

2.3. Environments

The three environmental conditions were: urban – quiet residential streets with low levels of traffic; green – country park within the city; blue – footpath besides a canal with a range of natural vegetation (Fig. 1). Environments were selected on the basis of several criteria: less than 15-min drive from the University; rated as 'natural' or 'urban' (depending on condition) and 'pleasant' based on responses to a separate online image survey (Gidlow, Jones, Hurst, & Masterson, 2013); comparable gradient to minimise differences in exercise intensity; and unlikely to have large numbers of people to reduce the risk of incidental social interaction. The roads in the urban environment were residential, had traffic levels that were too low for official measurement and classification in the UK (i.e., <500 cars/day), and noise levels comparable to the natural environments (urban 50.56 ± 4.25 dBa, green 47.47 ± 2.94 dBa, blue 45.60 ± 1.46 dBa, average of two 15-min recordings at

Fig. 2. Flow diagram for each day of data collection.

representative points in each environment measured by a Precision Gold N05CC Sound level meter). The low levels of noise in all environments provided confidence the slightly higher readings in the blue and urban environments should not have been sufficient to promote a stress response in the urban environment.

2.4. Measures

Baseline profiling. Participants completed a series of

questionnaires to profile: socio-demographics (age, gender, ethnicity, education, employment status, postcode); self-reported health using the Short-Form 12 (SF12v2 used to determine Physical and Mental Component Scores, where scores below/above 50 indicate health that is below/above average, respectively) (Quality Metric, 2006); Perceived Stress Scale (PSS) (Cohen & Williamson, 1988); nature-relatedness using the NR-6 Nature-relatedness scale (Nisbet, Zelenski, & Murphy, 2009). The latter was included to explore whether the extent to which individuals felt connected

with the natural world could explain differential responses to natural environments.

2.4.1. Responses to the natural environment

- Total Mood Disturbance (TMD) was assessed using the BRUMS (Terry, Lane, & Fogarty, 2003), a widely used and validated abbreviated version of the Profile of Moods States (McNair, Lorr, & Droppleman, 1971), where lower values indicate better mood.
- Cognitive function was assessed through the Backward Digit Span (BDS), a measure of working memory used by others in this area (Berman et al., 2008). Participants were read a sequence of three to nine digits and asked to repeat them in reverse order. This was repeated up to 14 times (two repetitions of each digit span) and stopped after two consecutive failures, with the length of the longest correct sequence providing a measure of cognitive function (i.e., higher scores indicate better cognitive function).
- Restoration experience was measured through an abbreviated six-item version of the Restoration Outcome Scale (Korpela, Ylén, Tyrväinen, & Silvennoinen, 2008), where higher scores indicate a more restorative experience. The scale included items, such as 'I feel calmer', 'After visiting this place I feel restored and relaxed', and 'My concentration and alertness clearly increased', to provide a measure of the perceived restorative experience of visiting each environment.
- Salivary cortisol was measured as a physiological marker of stress. Cortisol concentrations were determined from saliva samples collected using synthetic swabs, which participants placed beneath their tongue for 2 min. All samples were centrifuged at 3000 rpm for 15 min, divided into two samples and stored separately at -80°C until batch analysis (Salimetrics Ltd. High Sensitivity Salivary Cortisol Enzyme Immunoassay Kit). Salivary cortisol concentrations (nmol/l) provided an objective measure of stress, with higher values indicating higher stress.
- Ambulatory Heart Rate (HR) and HRV data were collected using the eMotion monitor (<http://www.megaemg.com/products/emotion-hrv>) (Heikkinen, 2012). HR was included as an objective measure of exercise intensity. HRV reflects the interplay between the excitatory sympathetic nervous system, which is dominant at times of stress and the inhibitory parasympathetic nervous system, which is dominant in periods of relative safety and restoration (Appelhans & Luecken, 2006). Data processing in Kubios software (<http://kubios.uef.fi>) included: artefact correction (Tarvainen, Niskanen, Lipponen, Ranta-Aho, & Karjalainen, 2014) removal of very low frequency trend components using a smoothness priors detrending method (Tarvainen, Ranta-Aho, & Karjalainen, 2002), and interpolation of the RR series. HRV indicators used in analysis included mean RR interval (time between each heart beat), standard deviation of normal-to-normal intervals (SDNN), and low frequency (LF, 0.04–0.15 Hz) and high frequency (HF, 0.15–0.4 Hz) powers from Fourier spectra. For each HRV variable, the percentage coefficient of component variance (%CCV) was calculated to obtain %CCV to control for differences in RR interval as a result of different exercise intensities (Højgaard, Holstein-Rathlou, Agner, & Kanters, 1998).
- Rate of Perceived Exertion (RPE) was measured at 5-min intervals during the walks using the Borg Scale (Borg, 1990), to provide a measure of participant-rated exercise intensity.

2.5. Statistical analysis

For each of the outcome measures, with the exception of

restoration (measured at T2 only), a three-by-three repeated measures ANOVA was used to investigate the effects of time (baseline, immediately post and 30 min after leaving the environment), environment (urban, green, blue) and time by environment interactions. If there was a significant interaction, this was explored using simple main effects via one-way ANOVA comparing environments, and where environment was significant, this was explored using paired contrasts, via t-tests with Tukey's HSD used to control for multiple testing. Where there was a main effect of environment, but no interaction with time, this was again explored via paired contrasts. Physiological measurements required transformation to meet parametric analysis assumptions (cortisol concentration was square-root transformed and HRV parameters were log-transformed). Where assumptions of sphericity were violated, adjusted degrees of freedom using the Greenhouse-Geisser estimate were reviewed. The target sample size was 40. This was based on: an estimated 20–50 participants required to detect a medium-large effect, using a within subjects ANOVA with three conditions ($df = 2$), power of 0.8 and an alpha level of 0.05; the practical considerations of collecting all data in temperate conditions. Analyses were undertaken in IBM SPSS version 22.

3. Results

3.1. Participants

Eighty-eight screening questionnaires were completed. Seventeen individuals were excluded as ineligible (unable to attend appointments $n = 5$; on medication $n = 6$; long-term illness $n = 2$; medication and long-term illness $n = 3$; smoker $n = 1$) and 31 declined to take part or did not respond to further communication. Of the 40 participants who started the study, two were lost to follow-up and did not visit all environments; 38 completed and were included in analysis (23 male, 15 female; $M_{\text{age}} = 40.9 \pm 17.6$). Participants were predominantly White British (92.1%) and the majority were in full-time work (29%), students (29%) or retired individuals (24%); the remainder comprised unemployed, home-keepers and those in part-time work. Relatively good health of the sample was confirmed in terms of self-reported health (Physical Component score = 55.5 ± 5.08 ; mean Mental Component Score = 52.3 ± 7.8), Body Mass Index ($25.4 \pm 5.0 \text{ kgm}^{-2}$) and mean PSS score (11.1 ± 6.5).

3.2. Walking exposure

Mean RPE was slightly higher in the green (10.2 ± 1.5) and urban (10.0 ± 1.5), compared with the blue environment (9.0 ± 1.5), but all were in the very light to light intensity range. Heart rate data confirmed that participations were walking at moderate intensity; i.e., 55–69% of maximal HR (Pollock et al., 1998). As a percentage of theoretical maximal heart rate ($\text{HR}_{\text{max}} = 220 - \text{age}$), mean % HR_{max} was comparable in each environment (urban $59.97 \pm 8.86\%$; green $62.18 \pm 9.56\%$; blue $58.67 \pm 9.35\%$).

3.3. Psychological responses to environments

Mood improved from baseline (T1) in all environments, with a significant main effect of time on TMD, $F(1.37, 46.41) = 6.40$, $p = .009$, $\eta^2 = 0.07$, post-walk (T1 to T2), $F(1, 34) = 8.77$, $p = .006$, $\eta^2 = 0.23$, and 30-minutes after leaving the environment (T1 to T3), $F(1, 34) = 5.29$, $p = .028$, $\eta^2 = 0.16$. There was no significant main effect for environment, $F(2, 68) = 1.77$, $p = .178$, $\eta^2 = 0.02$ and no significant environment*time interaction effect, $F(2.91, 98.89) = 1.01$, $p = .389$, $\eta^2 = 0.005$ (Table 1).

There was also a significant main effect of time on cognitive

	T2	6.84 (2.52)	-5.57 (4.10)	3.77 (1.79)	—	—	—	—
	T3	6.45 (2.35)	-5.34 (3.67)	3.41 (1.64)	6.13 (3.48)	0.02 (0.01)	0.03 (0.02)	2.13 (0.77)

TMD, Total Mood Disturbance; %CV, percentage coefficient of component variance; HFCCV, percentage coefficient of component variance for high frequency powers; LFCCV, percentage coefficient of component variance for low frequency power; LFCCV:HFCCV, ratio between LFCCV and HFCCV.

function, $F(2, 74) = 3.39$, $p = .039$, $\eta^2 = 0.01$, but no significant main effect for environment $F(2, 74) = 0.926$, $p = .401$, $\eta^2 = 0.01$. Additionally, a significant environment*time interaction effect was evident, $F(4, 148) = 2.89$, $p = .024$, $\eta^2 = 0.02$, such that improvements in cognitive task performance persisted at T3 following exposure to both natural environments, but reduced to below baseline levels in the urban condition: Blue vs. Urban (T1 vs. T3), $F(1, 37) = 9.26$, $p = .004$; Green vs. Urban (T2 vs. T3), $F(1, 37) = 4.35$, $p = .044$ (Table 1, Fig. 3).

A significant difference in restoration experience was also found between environments following the 30-min walk, $F(2, 72) = 28.54$, $p < .001$, $\eta^2 = 0.21$ (Fig. 4). Follow-up contrasts showed that ratings of restoration experience were significantly higher in the natural compared with urban environments: Green vs. Urban, $t(36) = 5.87$, $p < .001$, $\eta^2 = 0.49$; Blue vs. Urban, $t(36) = -6.43$, $p < .001$, $\eta^2 = 0.57$.

The influence of participants' trait nature-relatedness was explored for outcomes where a significant environment effect was observed. Nature-relatedness was not significantly correlated with restorative experience in the green or blue environments (all $p > .069$), or with changes in cognitive function (all $p > .224$). Collectively, the results suggested no potential relationship linking

Fig. 3. Mean change in cognitive function (backwards digit span task) from baseline to 60-min post exposure follow-up by environment.

Fig. 4. Mean restorative experience, as measured by the ROS, by environment.

nature-relatedness with restorative experience or cognitive function, so further analyses were not warranted.

3.4. Physiological responses to environments

A significant main effect of time on cortisol concentration was found, $F(1.37, 48.01) = 82.83$, $p < .001$, $\eta^2 = 0.29$. Significant reductions were observed in all environments at T2, $F(1, 35) = 83.80$, $p < .001$, $\eta^2 = 0.71$, and T3, $F(1, 35) = 98.23$, $p < .001$, $\eta^2 = 0.73$ (Table 1). There was no significant main effect for environment, $F(2, 70) = 0.195$, $p = .823$, $\eta^2 = 0.002$ and no significant environment*time interaction effect, $F(2.52, 88.30) = 0.801$, $p = .478$, $\eta^2 = 0.004$. Tests were run for males and females separately, but there was no evidence of differential cortisol response by gender (data not shown).

Heart rate variability data were inconclusive, showing no consistent patterns by time or between environments for any of the HRV indicators from baseline to T3 (Table 1). Differences in respiration rate were explored through HF Peak Power (Hz) to determine possible confounding effects, but environment*time effects were not evident (all $p > .194$).

4. Discussion

Our data suggest that walking in a natural environment confers greater benefit for restorative experience and cognitive function, which persisted for at least 30 min after leaving the environment, when compared with a similar walk in a pleasant urban environment. However, no differences in self-reported mood, or physiological indicators of stress (cortisol and HRV), were observed.

Perceptions of greater restoration following natural environment visits are consistent with the literature (Beil & Hanes, 2013; Bodin & Hartig, 2003; Korpela, Ylén, Tyrväinen, & Silvennoinen, 2010). Significant environmental differences in cognitive function did not manifest until 30-min later when participants had left the environment. In relation to the ART, researchers have shown changes in performance on cognitive tasks do not consistently emerge within 15–20 min of natural environment exposure (Laumann, Gärling, & Stormark, 2003), but are manifest after 50 min of engagement (Berman et al., 2008; Hartig et al., 2003). In our study, these changes were observed 60 min after first engaging with the natural environment (30 min after leaving). This has practical implications; for example, a lunchtime walk in a natural environment could help to improve cognitive performance at work for at least 30 min after returning.

We did not find environmental differences in indicators of stress assessed by self-reported mood and cortisol. The lack of mood effect was consistent with some studies comparing responses to walking in natural and urban environments (Johansson, Hartig, & Staats, 2011; Kinnafick & Thøgersen-Ntoumani, 2014). It also supports data showing mood benefits of walking at a self-directed pace (Ekkekakis, Parfitt, & Petruzzello, 2011). Where field-based studies have reported greater improvements in mood following exposure to natural, compared with urban environments, these are potentially attributable to a negative response to the urban condition (Hartig et al., 2003; Lee et al., 2011; Tsunetsugu et al., 2013). Reductions in cortisol were also observed in all environmental conditions, which is consistent with the lack of environmental effects found in the published literature (Beil & Hanes, 2013; Lee et al., 2011; Tyrväinen et al., 2014). Where beneficial cortisol responses have been reported, there are recognised limitations, such as absence of baseline data (e.g., Park et al., 2010), or other potential confounders, such as differences in activity levels across environments (e.g., Van den Berg & Custers, 2010). The magnitude of reductions in cortisol we observed over 30 min were greater than would be expected from the typical diurnal pattern (Doane, Chen, Sladek, VanLenten, & Granger, 2015; Edwards, Clow, Evans, & Hucklebridge, 2001), which suggests that there were instorative effects although this remains speculative in the absence of an inactive control condition. In any case, as improvements were observed across all conditions, our cortisol data did not support the natural versus urban benefits reported elsewhere.

Heart rate variability data did not show any differences in environmental response, or any consistent patterns over time. Significant natural-urban environment differences in HRV have been reported in laboratory settings using images and 3-D simulations (Annerstedt et al., 2013; Brown et al., 2013; Gladwell et al., 2012). Field-based research has suggested favourable responses to walking and sitting in forest versus busy urban environments (higher HF; lower LF:HF). However, in the absence of baseline data, caution is required (Park et al., 2010; Tsunetsugu et al., 2013), and where change from baseline has been reported, a negative response to the busy urban environment, rather than positive natural response, is evident (Lee et al., 2011). Based on our data, 30-min of walking or low intensity physical activity in natural or pleasant urban environments does not significantly alter HRV. However, as noted below, the amount of noise in HRV when taking

measurements in the field, rather than in laboratory conditions, might negate our ability to detect subtle environmental responses using HRV.

In our sample of non-stressed, healthy adults who visited natural and pleasant urban environments, our findings are better explained by ART than SRT. Specifically, the environmental differences that emerged were for restorative experience and cognitive function, the latter emerging 60 min post-initial exposure. That we observed stress-reducing effects in all environments points to the salutogenic effects of being physically active, even at low intensity. The improvements to mood across all environments and of cognitive function in the natural environments may reflect the motivational properties of physical activity (Ekkekakis, 2003). Also, the physical activity might have had such a dominant influence that more subtle environmental effects were not detected. This potential limitation is particularly relevant to HRV. Although we used the %CCV indices to account for differences in heart rate (i.e., exercise intensity) and explored differences in respiration rate, additional controls were not feasible. Further we recognise that it was not possible to adhere to recommendations for HRV measurement. Efforts to make the participant experience as *normal* as possible and to avoid boredom, meant that we were unable to measure HRV during timed breathing for 5-min periods, and used 1-min segments of untimed breathing as used elsewhere (Lee et al., 2011).

Other limitations are acknowledged. First, it was not feasible to explore the full range of different environments or to recruit a fully representative sample, which limits generalisability. Rather, we recruited a range of healthy, non-stressed adults and selected environments with specific attributes (as detailed earlier). Second, while environment visits were only conducted in temperate conditions, some variability in weather between days could have influenced participant experiences. Third, it would have been preferable, but not feasible to standardise exercise intensity across all participants and environments. As detailed earlier, self-paced walking was chosen to optimise participant experience and ecological validity, whilst helping to ensure that exercise was mostly of light intensity (so avoiding problems of psychophysiological impacts of higher intensity activity). Fourth, the researcher walking with the participant was necessary, but could have made the experience feel somewhat unusual. Measures to limit this included having the same researcher-participant pairing throughout and randomising the order of exposures (to negate issues of the experience feeling less unusual on subsequent days).

Our study was concerned with the potential *instorative* effects in individuals who are not stressed or cognitively fatigued (Hartig, 2007), and used a comparator urban environment that was not stressful or unpleasant. This comes from a public health perspective that engagement with natural environments may have wider public health benefits than facilitating recovery from stress. The applicability of research in this area could be enhanced by replicating how people typically engage with natural environments. In particular, people tend to visit the same natural environments repeatedly so understanding whether the benefits of a single exposure are attenuated, maintained or increased is an area of future focus. Further research could include a broader range of urban and natural environments to begin mapping environmental characteristics to stress-reducing capacity. For example, a recent study has shown that the relationship between tree coverage and stress recovery was non-linear, such that stress recovery improved with increasing tree coverage up to a point, but decreased thereafter (Jiang, Chang, & Sullivan, 2014). Exploring the longevity of the positive effects on cognitive function from being physically active in a pleasant natural environment would be another area for future research, specifically to determine if these extend beyond the 60 min post-engagement shown in the present study.

Overall, our findings indicate that light intensity physical activity in a natural environment confers greater benefit for restorative experience and cognitive function, which persisted for at least 30 min after leaving the environment, when compared with a similar walk in an urban environment. For immediate improvements in measures of well-being you can put your best foot forward in a pleasant urban or natural environment, but for the additional improvement in cognitive function, choose a natural environment.

Funding sources

This study was conducted as part of PHENOTYPE project (Positive Health Effects of the Natural Outdoor Environment in Typical Populations in Different Regions in Europe) (www.phenotype.eu) funded by the European Commission Seventh Framework Programme (Grant No. 282996).

Author contributions

The manuscript was written through contributions of all authors. All authors have given approval to the final version of the manuscript. Study conception and design was led by CG, MJ, GH and MN. Data collection was completed by GH and DM. Data analysis involved GH, DM, CG, MJ, DCC, MT and GS.

Acknowledgement

The authors would like to thank Denise Figgins for laboratory support and all study participants.
